A sense of perspective

During consultation with a patient recently, I was confronted with an elderly, infirm man who had designed a small plastic splint which he wore on the palmar surface of the proximal phalanx of the right ring finger as management for triggering. The tensile recoil strength within the low profile splint maintained the proximal interphalangeal joint in about 20 degrees of flexion and, following active flexion, returned the finger passively to this position. I asked whether the wearing of this splint interfered with his function. The response was no. I then asked whether he would wish either an injection or an operation for the condition which, in his words, was causing no loss of function, nor pain for that matter. Receiving a response in the negative, I then confronted him with clinical presentations which reminded me of something I have never seen before. In these cases I find it helpful to consider a number of questions: 1) is the part too large or are there too many (digits); 2) is the part too small or are there too few (digits); 3) is there deviation (deformity) in any plane; 4) are joints unstable or immobile? The answers to these questions lead to a logical surgical approach, that being the removal of extra tissue or parts; the addition of tissue or parts; correction of deformity (perhaps multi-planar); stabilisation of unstable joints and an attempt to improve motion. Of course, the last of these is the most difficult, except perhaps in the case of a locked trigger digit.

We should be grateful for our good fortune and should remember to apply a sense of perspective to all aspects of our lives.”

However, before deciding on whether any form of treatment, including surgery, is indicated, perhaps the appropriate question to ask is whether a treatment is being offered because the physician sees something wrong or whether the treatment offered will improve the circumstances of the patient with minimal risk of complications. This is particularly so for difficult congenital presentations.

My elderly, infirm patient with the trigger digit, suffering no functional loss with the use of his home made splint, and no pain, did not need my intervention, at least not for physical reasons.

A sense of perspective is helpful, even when considering the most minor of clinical problems. A sense of perspective becomes more necessary when confronted with major tragedies, one’s own or those of others. At these times, a focus on the importance of our own medical lives may seem misplaced. One such recent tragedy was the lamentable loss of our colleague Philippe Saffar, from France. Another is the loss of Toshihiko Ogino from Japan. Their wives, Michele and Tomoko respectively, and their families have lost a major part of their lives and our hearts go out to them. We have lost the most admirable of colleagues.

We are fortunate that, in a relatively small medical community, we are able to meet and interact with so many different people from different places, through congresses, medical writing, travel, and electronic communications. We are blessed with opportunities unavailable to most. We should be grateful for our good fortune and should remember to apply a sense of perspective to all aspects of our lives.
Ezio Morelli was born in Montecastello Vibio, (Perugia) Italy on July 2, 1923. He graduated in Medicine and Surgery in July, 1948. In 1951, he did post-graduate training at the University of Munich School of Medicine under Professor Max Lange. In 1952 and 1956 he studied at the Unfallskrankenhaus in Vienna under the supervision of Professor Böhler. Dr. Morelli specialized in Orthopaedic Surgery and Traumatology in 1951, in Occupational Medicine in 1954, and in Plastic Surgery in 1961 and qualified for university teaching in Orthopaedics in 1962 and Plastic Surgery in 1967. Professor Morelli headed the Division of Plastic Surgery and Hand Surgery of Legnano Hospital from 1964 to 1988.

Since 1948, Professor Morelli has worked predominantly in the field of hand surgery, vascular microsurgery and peripheral nerve surgery and later as a surgeon at the S. Ambrogi Private Hospital in Milan. His micro-surgical contributions became internationally known, and because of putting the city of Legnanesi on the world map, the ‘Piazza Ezio Morelli’ was named after him.

Professor Morelli has published 140 papers and has collaborated with many Italian and overseas universities in holding conferences and updating courses. Professor Morelli was Past-President of the Italian Society of the Hand. He was awarded the Gold Medal of the Public Health for his outstanding work by the Minister of Health.

His humanity and classic culture have earned him the esteem and friendship of many hand surgeons at home and abroad.

In 1995 he was honoured as “Pioneer of Hand Surgery” by the International Federation at its sixth Congress in Helsinki, Finland.

Dr. Omer graduated in medicine from the University of Kansas, and completed a residency at Brooke Army Medical Center while earning a master of science in orthopaedic surgery from Baylor University. After preceptor periods with Adrian E. Flatt and Daniel C. Riordan, Colonel Omer organized the first designated Section of Hand Surgery in the U.S. Armed Forces after World War II in 1962. He was the first career officer of the U.S. Armed Forces to be elected a member of the American Society for Surgery of the Hand. Colonel Omer remained on active duty from 1950 to 1970 and served as military consultant in hand surgery and orthopaedic surgery to the Surgeon General of the U.S. Army.

Dr. Omer is recognized for his series of unique contributions that initiated certification of hand surgery in the United States. The Certificate of Added Qualifications in Surgery of the Hand was formally initiated while Dr. Omer was President of the American Society for Surgery of the Hand (1978-79); subsequently, the Certificate was recognized while Dr. Omer was Chairman of the Joint Committee for Surgery of the Hand (1984-92), representing the American Boards of Orthopaedic Surgery, Plastic Surgery, and Surgery. The first national examination for certification was held in 1989 when Dr. Omer was the Immediate Past-President of the American Board of Orthopaedic Surgery. In recognition of this accomplishment, Dr. Omer was awarded a special plaque in 1989 by the American Society for Surgery of the Hand.

Dr. Omer served as Professor and Chairman of the Department of Orthopaedics and Rehabilitation at the University of New Mexico Medical Center from 1970 to 1990. Dr. Omer established the first formal academic Division of Hand Surgery in North America in 1970, with an active fellowship program since 1972. His leadership in American orthopaedics was recognized by the Presidency of the Western Orthopaedic Association, 1981-82, and the Presidency of the American Orthopaedic Association, 1988-89. Dr. Omer was President of The Sunderland Society in 1981-82.

Dr. Omer has presented more than 950 papers at 465 meetings in 25 countries, emphasizing the management of peripheral nerve problems. He has published more than 130 peer-reviewed papers, two books, and 60 chapters. Dr. Omer is a honorary member of seven hand surgery societies. Dr. Omer served as Executive Director of the American Orthopaedic Association, 1990-93.

George E. Omer was honoured as "Pioneer of Hand Surgery" by the IFSSH at its sixth Congress in Helsinki, Finland on 3 July 1995.
2015 IFSSH DELEGATES’ COUNCIL MEETING

The annual IFSSH Delegates’ Council Meeting was held in Seattle on September 10th, in conjunction with the annual meeting of the American Society for Surgery of the Hand. 32 of the 55 member societies were represented at the meeting and we thank these delegates for their contribution.

At this meeting, the Delegates unanimously adopted the newly modified bylaws of the IFSSH, as well as the proposition by the Executive Committee of registering our organization as an international non-for-profit organization based in the State of Illinois, USA. The IFSSH Charter had been initially registered in 1990 in Puerto Rico by the late Dr Miguel Vargas. The need for reconsidering the location of that registration had been raised in previous Delegates’ Council meetings to optimize our legal and financial status.

The Delegates’ Council accepted the membership application of the Kuwait Society for Surgery of the Hand. We welcome this society into the Federation and look forward to inviting its delegate and members to participate in future activities.

Eduardo Zancolli reported on the progress of the IFSSH triennial congress, to be held in Buenos Aires, October 24th-28th 2016. The scientific and social programmes have been prepared and promise a stimulating and exciting congress. Registration opens on November 1st 2015. Detailed information is available on the new congress website - http://www.ifssh-ifsh2016.com/

The 2016 congress will coincide with the 50th anniversary of the foundation of the IFSSH. We hope all members of the IFSSH societies will join us to celebrate this milestone.

IFSSH - SOUTH ASIAN REGIONAL COURSE IN HAND SURGERY

The IFSSH recently provided a US$20,000 grant to assist with the conduct of a regional hand surgery course in South Asia. The following report was submitted by Dr. S. Raja Sabapathy, the Course Chairman:

The IFSSH sponsored South Asian Regional Live Hand Surgery Workshop was held at Ganga Hospital auditorium, Coimbatore, India, from 3rd to 5th July, 2015. It had prominent overseas faculty including the IFSSH President Dr. Michael Tonkin. Dr. Don Lalande from Canada, Dr. Goo-Hyun Baek from South Korea. Dr. P.C. Ho from Hong Kong and Dr. Amit Gupta from USA were the overseas faculty and they were joined by the Ganga Hospital team of doctors.

293 delegates participated in the course and of them 37 were from overseas belonging to 18 nations. The conference was held in the comfortable Ganga Hospital auditorium. 24 live surgeries were demonstrated. It covered a wide range of procedures like cleft hand, syndactyly, brachial plexus nerve transfers, wrist arthroscopy, wide awake surgical demonstrations, tendon repair, tendon transfers and carpal injuries. At any one time two surgical procedures were demonstrated with the moderators helping the delegates to interact with the Surgeons. The demonstrations were so intensive that the hall was full till the very end. Every session started with 2 didactic presentations from the faculty and a total of 10 lectures were delivered.

It also had good social programmes. We had Banquet Dinners on the evening of 3rd and 4th July. On the evening of 4th July, Dr. P.C. Ho with his Harmonica and Dr. Amit Gupta with the Indian Drums (Tabala) entertained the people with the fusion of western and Indian music which provided an opportunity for the delegates to interact with the faculty.

The feedback that we got from the delegates were very complimentary both to the content of the course and the organization. Together it was a very rewarding experience to the delegates.

Hand and Wrist Biomechanics International (HWBI) Awards

We are pleased to report that the HWBI, an allied organization of IFSSH, in their 9th symposium held in Milano, Italy, on June 16th-17th 2015, awarded four scholarships to encourage four investigators pursue research in hand and wrist biomechanics. The scholarships were generously sponsored by the ISB, HWBI, and William H. Seitz, MD Research Fund. The award committee selected this year’s winners based on the abstract submissions to that symposium. The award winners were Joseph N. Gabra (USA), Benjamin Goislard de Monsabert (France), Faes D. Kerkhof (Belgium), and Giovanni F. Solitro (USA). For more information about the HWBI and its events, please visit the website at www.hwbi.org.

FUTURE MEETINGS

A detailed list of national and regional hand surgery meetings is available on the IFSSH website.

The triennial IFSSH Congresses are as follows:

XIVth IFSSH – XIIth IFSHT Congress – Berlin, Germany May, 2019

Hand and Wrist Biomechanics International (HWBI) Awards

THE NATURAL HISTORY OF THE FOREARM

OLIVIER DELAERE M.D. (BELGIUM)

ABSTRACT
The natural history of the forearm started in water within the fins of some Devonian fishes. Some 385 million years later, through amazing adaptations, the forearm bones allowed the tetrapods world to colonize every other kind of biotopes on Earth.

Initially devoted to locomotion in amphibians, birds and reptiles, the forearm develops more ambitiously in the mammalian lineage. Adopting first an upright limb posture and bipedalism thereafter, the Hominidae forelimb acquires a 30 million year period between the end of the Devonian and the beginning of the Carboniferous periods. During this time, primitive tetrapods invaded land and their limbs replaced the tail as the main organ of propulsion (Hutson, 2006).

Chapter 1: AT THE ORIGINS...
The natural history of the forearm on planet Earth is a nearly 400 million years long journey. Indeed, the earliest witnesses of a forearm skeleton are some fossil fishes of the Devonian. Fortunately, some of them like Eusthenopteron foordi remain perfectly preserved and the anatomy of their pectoral fin clearly shows the presence of a radius, an ulna and a humerus (fig.1). In fact, Eusthenopteron foordi is not a real fish anymore, it has internal nostrils, different teeth and most probably lungs, but the general shape of its body still reflects a fully aquatic lifestyle (Jarvik, 1980).

10 million years later, signs of an amphibian way of life are more obvious. Tiktaalik roseae (fig.1) can be considered as a true transitional species; it still has scales and fins, but now it has a neck, a flat head and eyes on top of it, able to see what happens above water...

According to Neil Shubin, Tiktaalik roseae was able to pull itself onto the shore for brief periods, thanks to a strong pectoral girdle and a primitive wrist, able to bend the distal fin to lie flat on the ground like seals, for example (Shubin et al., 2006).

It is surprising to see that the first real tetrapods, with hands and feet instead of fins were still aquatic creatures like Acanthostega gunnari (fig.1). These odd hands, with 8 webbed fingers suggest that this early tetrapod was mainly using its arms, forearms and hands like paddles and probably nothing more (Coates and Clack, 1990; Long and Gordon, 2004).

The so-called "Romer's gap" is a 30 million year period between the end of the Devonian and the beginning of the Carboniferous periods. During this time, primitive tetrapods invaded land and their limbs replaced the tail as the main organ of propulsion (Hutson, 2006). Until recently, this gap was one of the first challenges of the forearm bones.

Pro-supination or rotation of the forearm is an older ability than one might think: it probably started in sarcopterygian fishes, but it was quite restricted, even in early aquatic tetrapods (Pierce et al., 2012). Land invasion will require a bigger range of motion...

Chapter 2: THE SPRAWLING FOREARM
To understand the anatomy of a sprawling forearm, and how the reptile ulna and radius are able to pronate, one has simply to observe the forelimb of a contemporary species: the Varanidae.

The schematic model in Fig. 2 shows the main features of a typical reptile forearm.

Ulna and radius are straight, divergent and there is no distal radial joint. The uncorpal joint is of ball and socket type and the main feature is that whatever the rotation of the forearm, the ulna and radius never cross each other (Haines, 1946). Like all the sprawling vertebrates, the varanus elbow is a bicondylar joint. There is no interosseus membrane (Haines, 1946; Landsmeer, 1983).

Upon close inspection, the radial head has an oblong shape, restricting axial rotation of the radius (Fig.3).

In fact, the main and original way for reptiles to rotate their forearm is to flex and extend the radius independently from the ulna (Hutson, 2010; Landsmeer, 1983) (Fig.3).

At the elbow level, the radialis condyle of the humerus extends further proximally, allowing a wider range of flexion of the radius compared with the ulna (Fig.3). Moreover, the radial flexion axis is orientated towards the ulna, both features helping the hand to keep a semi-prone position, whatever the locomotion phase (Hutson, 2010) (Fig.3). To stabilize the elbow, the proximal ulna is made of two condylar facets, separated by a
marked crest and articulating not only with the ulnar condyle but also with the ulnar side of the radial condyle of the humerus (Hutson, 2010).

At the wrist level, contrary to the simplified drawing in Fig. 2, only the ulno-carpal joint is really of ball and socket type and can be considered as the pivot point of the wrist. The radio-carpal joint anatomy does not allow significant rotation (Landsmear, 1983).

Interestingly, even if some of these anatomical features are very distinctive of the sprawling species, the functional plan of the tetrapods forelimb seems to share a common principle: it is made of two functional units. The first one is the humero-ulnar segment, allowing a stable and “hinge-like” elbow joint. The second one is the radius-carpus-hand segment, allowing a stable wrist and articulating with the humero-ulnar unit with a kind and range of motion depending on species (Hutson, 2010).

Chapter 3: A FLYING FOREARM

INHERITED FROM DINOSAURS

Soon after land colonization, stem amniotes will split into different lineages and try to adapt themselves to other kinds of biotopes on Earth. In the history of reptiles, some in the dinosaur group will abandon the sprawling gait to more efficient ways of locomotion. Eoraptor for example, one of the world’s earliest dinosaurs, is already bipedal. Oddly enough, from the mid-Jurassic, within a family of these running lizards, the aptly named Dromaeosauridae, something strange will happen within the forelimb. At the hand level, two fingers disappear. At the wrist level, the radiale bone or “scaphoid” becomes wedge-shaped and the midcarpal joint becomes a trochlea (Sullivan et al. 2010). These anatomic features lead to a progressive ulnar shift of the hand. The forearm itself loses its ability to rotate. The radius migrates proximally to lie side by side with the ulna along the elbow flexion plane. In some specimens like Microraptor Gui, limbs and tail are covered with feathers (Sullivan et al. 2010) (Fig. 4). As these strong indicators tend to suggest, we are touching here on the origins of birds!

Within a flying forearm, ulna and radius need to be stable and to link elbow and wrist flexion during upstroke, and extension during downstroke. This critical synchronization is ensured by the “drawing parallels” mechanism, even if the role of extensor metacarpal and flexor carpi ulnaris muscles, through a tenodesis effect, is considered even more important (Vasquez, 1992) (Fig. 5).

Unlike the maniraptoran dinosaurs, the bird wings include an additional bone between the ulna and carpometacarpus, named “cuneiform” (Fig. 5). By preventing the manus from hyperpronating during downstroke and by rotating the manus towards the body during upstroke, the cuneiform probably offers a crucial advantage to master the airs (Vasquez, 1992).

Chapter 4: REACHING AN UPRIGHT LIMB POSTURE

By placing hands and feet closer to the center of gravity, straight limbs under the body provide some biomechanical advantages compared to the sprawling posture. This implies some fundamental changes, including shifting humerus and femur from a horizontal to a vertical position, and pointing elbow backward and knee forward (Humphry, 1876; Radinsky, 1987) (Fig. 6). But if internal rotation of the hindlimb is of no consequence for the foot, external rotation of the forelimb tends to put the hand in supine position, which is unsuitable for locomotion. On the other hand, the sprawling forearm model, with a straight radius only able to sway forward and backwards does not allow a reorientation of the hand of such magnitude.

The most efficient solution to that issue will be provided by the therian mammal lineage. In therian mammals, the radius curves and crosses over the ulna: from the elbow to the wrist, it moves from a lateral to a medial position. By this half-turn, the radius is now able to put the wrist and hand in full pronation (Humphry, 1876) (Fig. 6&7). An almost exclusive capacity in the whole world of tetrapods, only shared by the funambulists chameleons (Hutson, 2010).

Moreover, by developing proximal and distal radio-ulnar joints of trochoid type, some mammal species will be able to make this half-turn back.

The main anatomical features of a therian mammal forearm are summarized in Fig. 7: a straight ulna, a curved radius, a rotational axis from radial head to ulnar head, a radial neck just along this axis, a longer forearm than reptiles and bones crossed in pronation, an interosseous membrane, the presence of a capitellum and trochlea instead of a bicondylar elbow, and finally more or less developed proximal and distal radioulnar joints (Haines, 1946).

By the late Triassic, parasagittal gait and erect posture of the forelimb were also adopted by non-mammalian quadrupeds on Earth. Amongst the Dinosaurs, the Sauropods suborder remains a prime example. But the way they reoriented their hands is less ambitious; at the forearm level, the whole radius shifts from an antero-lateral to an antero-medial position in relation to the ulna (Bonnan, 2003) (Fig. 8). Proximally, the radial epiphysis is of triangular shape and articulates inside a deep triangular fossa on the anterior face of the ulna (Fig. 8). The proximal ulna develops an anterolateral process, most probably to support the mechanical stresses on the lateral part of the elbow (Bonnan, 2003) (Fig. 8). As a general rule for non-mammal tetrapods, this forearm shifting process is unable to achieve a full pronation of the hand (Hutson, 2010). Moreover, such a model does
Chapter 5: THE VERSATILITY OF THE MAMMAL FOREARM

Provided with decisive anatomical improvements, including homeothermy, high metabolic rate, hair, diaphragm, four-chambered heart, three middle ear bones or neocortex, mammals will be able to occupy an extraordinary variety of substrates on Earth (Polly, 2007; Radinsky, 1987).

Consequently, the mammalian forearm will adapt itself to a multitude of biological roles, and not only postural, but also feeding, exploratory, grooming or defense related behaviors (Salton and Sargis, 2008).

For obvious biomechanical reasons, fossorial (digging) species are distinguished by a long olecranon and short ulna and radius, cursorial (running) species by the converse (Liem et al., 2001-2; Polly, 2007; Salton and Sargis, 2008). Interestingly, the more specific task the forelimb has to perform, the more its anatomy moves away from its original design.

In highly cursorial mammals like horses, the hand is reduced to a single digit, as well as the forearm, which is mainly reduced to the radius. And this is not only to optimize speed, but also the cost of energy while running (Liem et al., 2001-2) (Fig. 9).

An ulna mainly reduced to an olecranon process and its distal part fused to the radius is also typical of the only flying mammal species: bats (Gatesy and Middleton, 2007). Like birds, the bat’s forearm is unable to rotate. Elbow and wrist joints move in the same plane.

But if birds flap an entirely rigid forelimb with a vestigial hand, bats flap a highly elastic wing made of 4 long and mobile metacarpals and fingers (Fig. 10), making them the most efficient flyers on Earth (Swartz et al., 2012). Moreover, unique feature among mammals, the bat’s forearm and hand bones have a low mineralization rate and become nearly cartilaginous at the distal wing to promote flexibility and lightness (Swartz et al., 2012).

In obligatory aquatic mammals like cetaceans, the forelimb is also remarkably modified. Like some reptiles which reverted back to aquaticism in the early Jurassic period (Fig. 11), humerus, radius and ulna shorten and lose their morphological differentiation. The hand develops hyperphalangism.

Chapter 6: RUNNING AND CLIMBING CATS

The felidae family brings another interesting example of forearm adaptation and an enlightening exercise of compared anatomy.

At first glance leopards and cheetahs looks quite similar. Yet, the peculiar shape of their forearm make them completely different cats.

The main peculiarities of the cheetah’s forearm bones are highlighted in fig. 13. Ulna and radius are long and slender, typical features of a running species (Polly, 2007). The coronoid process is well developed, but this is common to all the mammals in upright position; the biomechanical advantage of that is obvious. The radial head is flat and poorly differentiated, as well as the distal ulna. At the wrist level, the distal radioulnar joint is made of a strong syndesmosis, locking the forearm in prone position (Hopwood, 1947). Moreover, a bony ridge at the radio-palmar aspect of the distal radial epiphysis restricts radiocarpal joint flexion and lateral deviation (Olale and Groenewald, 2003).

Compared with the cheetah, the leopard’s forearm bones are shorter but stronger (Fig. 14). The radius is more curved. The radial head is round and well developed. The ulnar head includes an articular surface with the distal radius; the radial head is flat and poorly differentiated, as well as the distal ulna. Bone insertions of the forearm muscles are distinctly marked on the ulna and radius, signs of greater strength, especially from pronator teres (Fig. 14) and supinator brevis.
The Lemuridae family is the most primitive of them. Their forearm has more in common with cheetahs than with leopards. There is no distal radio-ulnar joint and the distal forearm is stabilized by a strong syndesmosis (Lewis, 1965, Russel and Stern, 1998) (Fig. 15).

More evolved species like the Cercopithecidae start to develop not only a distal radioulnar joint like leopards but also a triangular disc, allowing the forearm to rotate up to 90° (Lewis, 1965; Russel and Stern, 1998) (Fig. 15).

Hominidae like gorillas or chimpanzees evolve towards a proximal retreat of the distal ulna and the interposition of a meniscus and a triangular disc between the ulnar head and the triquetrum and pisiform (Lewis, 1965) (Fig. 16). Thanks to that, big apes are now able to exceed 160° of pro-supination (Almquist, 1992; Russel and Stern, 1998).

A wide range of forearm rotation provides hominidae with new skills and abilities, like taking care of their young, gathering food or tool making and handling (Almquist, 1992). The latter faculty, long seen as exclusive to humans, also serves the interests of other primates; chimpanzees for example are known to use tiny twigs to fish for termites and even wooden spears to catch small monkeys (Pruetz et al., 2015).

Big apes and humans share not only an outstanding amount of similar behaviors. The genomes of chimpanzees and humans are so close that some scientists tend to bring them together into the same genus (Wildman et al., 2003). Nevertheless, they do differ in one important way: the human clade, the so-called “hominins” shifted to fully obligate bipedalism, and no doubt this step played a major role in the human forelimb evolution. The lack of locomotor constraints allowed the forearm joints to decrease their stability and increase their mobility (Drapeau, 2008). At the elbow for example, Fig. 17 shows how flat the human trochlea is when compared with brachiating apes like gibbons (Drapeau, 2008). Moreover, the humeroulnar joint is not fully congruous: the mid part of the ulnar trochlear notch is deeper than the humeral trochlear surface (Eckstein et al., 1993) (Fig. 17). The central part of the humeroulnar joint only comes in close contact when heavily loaded (Drapeau, 2008; Eckstein et al., 1993).

The annular ligament is a strong stabilizer of the proximal radio-ulnar joint but still allows some antero-posterior and lateral translation of the radial head during pro-supination (Galik, 2007). The distal radioulnar joint is also notoriously non congruent. The radius of the sigmoid notch is markedly bigger than the one of the ulnar head (Lees, 2009) (fig. 17). Unconstrained joints at the elbow and wrist level allow humerus, radius and ulna a subtle range of motion between each other, in particular lateral shift of the distal ulna and volar shift of the distal radius in full pronation, distal shift of the radius in full supination or proximal shift of the radius in elbow flexion (Kapandji IA, 1980, Lees, 2009; Quigley et al., 2014); this probably helps the human forearm to further increase its arc of rotation.

The proximal retreat of the ulna, initiated by the big apes, goes one step beyond in humans: the ulnar styloid loses contact with the triquetrum and pisiform (Lewis, 1965), further improving ulnar deviation of the wrist and tool using (Russel and Stern, 1998). The ulnocarpal gap is filled with a more and more specialized structure, the triangular fibrocartilage complex, to provide both mobility and stability of the ulnar part of the wrist (Lees, 2009; Palmer and Werner, 1981) (fig. 18).

As a result, the distal radius carries now about 80% of compressive load applied to the hand (Pfaeffle et al. 2000). To relieve the humeroradial joint, the interosseous membrane strengthens its central part; the interosseous ligament (fig. 18). As well as ensuring transverse stability of the forearm bones, this ligament also transfers axial stresses from the distal radius to the proximal ulna (Pfaeffle et al. 2000).

Unconstrained joints and highly specialized soft tissues make the human forearm the most sophisticated compromise between strength, mobility and stability. In the meantime, the human hand has evolved into an ultimate tool that the forearm will be able to place in space like never before to interact with its environment (Lees, 2009; Russel and Stern, 1998).

Chapter 7: BEYOND THE LIMITS OF LOCOMOTION

Within the climbing or “scansorial” species, one lineage will push the forearm development even further; the primates.

These anatomical variations have a huge impact on forearm function. Cheetahs are built to run, and to run very fast. Reaching an outstanding speed of 70 mph, they really need their forelimb to be stable and locked in full pronation. Therefore, their long, light, thin and stiff forearm is a perfectly adapted tool... but only when chasing a quick and mid-sized prey in open plains. Conversely, by their ability to rotate their paws and claws a quarter turn to half-supination, leopards benefit from an invaluable advantage; they climb more skillfully than any other big cat, which makes their hunting grounds extremely diversified. Moreover, the leopard’s forearm is strong enough to carry heavy prey on top of trees in places inaccessible to other predators (Fig. 14).

The proximal retreat of the ulna, initiated by the big apes, goes one step beyond in humans: the ulnar styloid loses contact with the triquetrum and pisiform (Lewis, 1965), further improving ulnar deviation of the wrist and tool using (Russel and Stern, 1998). The ulnocarpal gap is filled with a more and more specialized structure, the triangular fibrocartilage complex, to provide both mobility and stability of the ulnar part of the wrist (Lees, 2009; Palmer and Werner, 1981) (fig. 18).

As a result, the distal radius carries now about 80% of compressive load applied to the hand (Pfaeffle et al. 2000). To relieve the humeroradial joint, the interosseous membrane strengthens its central part; the interosseous ligament (fig. 18). As well as ensuring transverse stability of the forearm bones, this ligament also transfers axial stresses from the distal radius to the proximal ulna (Pfaeffle et al. 2000).

Unconstrained joints and highly specialized soft tissues make the human forearm the most sophisticated compromise between strength, mobility and stability. In the meantime, the human hand has evolved into an ultimate tool that the forearm will be able to place in space like never before to interact with its environment (Lees, 2009; Russel and Stern, 1998).
The principles are:

- Develop the question
- What are the alternatives
- What are the risks and complications
- Weigh up the advantages vs the disadvantages.

If you follow this rule you will always make a defensible, and usually very sensible, clinical decision.

One of my teachers (the late Robert Wheeler, Western Australia, supervisor of clinical training and head of Unit) used to say: An accident produces an uncontrolled injury inflicted for no purpose. Surgery is a controlled injury inflicted for a purpose.

Tony Pohl, director of Royal Adelaide Trauma unit says: A fracture is a soft tissue injury which involves bone.

Thank you for reading these little quotes. My personal opinion is that surgery is an art-form painted with a scientific brush.

Thanks for giving us a palette to work with.

Yours truly,
John Crock

IFSSH Scientific Committee on Flexor Tendon Repair

Chair: Esther Vögelin (Switzerland)
COMMITTEE: DAVID ELLIOT (UK), PETER C AMADIO (USA)

REPORT SUBMITTED MAY 2015

TRENDS IN FLEXOR TENDON SURGERY OVER THE LAST 10 YEARS
The results of flexor tendon repair in the hand have improved over the years, which is the result of a combination of improved surgical techniques and better rehabilitation. Further improvements may be on the way. Traditionally, to reduce muscle force on the repair, the wrist has been splinted in flexion after flexor tendon injuries. Now this practice has been called into question. There is debate about many details of technique. The central tenet of modern flexor tendon surgery is to repair and move divided flexor tendons within a few days of injury. The possibility of reducing the effect of adhesions on movement of the repaired tendon has been considered periodically but it remains to be proven whether, by drugs or other means, this can be useful routinely following flexor tendon repair. Like many other parts of hand surgery, when one looks more closely, one discovers that much that seemed fully understood is far from understood and what we have assumed to be based on hard fact often rests on opinion. Nevertheless, the results of flexor tendon repair in the hand have improved over the last twenty years, as a result of a combination of improved surgical techniques and better rehabilitation. This report examines trends in both.

REHABILITATION REGIMES Splinting and wrist position
At the present time, flexor tendon repairs are mobilised by most surgeons in a dorsal blocking splint as an additional safeguard against tendon rupture, with a definitive dorsal thermoplastic splint being applied 24-72 hours after surgery, whatever the technique of rehabilitation. While the interphalangeal joints are invariably allowed to fully extend, the precise degree to which these joints may extend in these splints varies from unit to unit. The degree of standardisation of splint construction possible in clinical practice probably belies such precision in print and the variability of the statements in the literature would suggest that the precise degree to which these joints are allowed to extend may not be of great significance. The degree of flexion of the wrist is probably less significant than previously believed. In an unpublished series of patients in Chelmsford/UK, 50 patients mobilised in the neutral wrist position had no increase in tendon ruptures with the same percentage of good and excellent results as this unit had reported previously with the wrist in the flexed position. Many units now splint the wrist in this position. A paper presented to the American Society for Surgery of the Hand (ASSH)[1] compared the results of similar flexor tendon repairs, treated after surgery with splints that either did or did not immobilize the wrist. Both splints blocked finger metacarpophalangeal joint extension at 30°. Both passive and active finger motion exercises were performed by the patients while wearing the splints. At both six and twelve weeks after injury, the short-splint group had significantly (p < 0.05) better
interphalangeal joint motion; at the twelve-week point, it was better by about 10°. Rupture rates were similar in the two groups. On the basis of this study, it may be reasonable to consider changing the traditional wrist-immobilization splinting regimen when treating patients with flexor tendon lacerations in the fingers.

Peck et al [2] compared the outcomes of patients with uncomplicated zone II flexor tendon repairs who had been rehabilitated using either the traditional forearm-based splint or the Manchester short splint (splint with no wrist component). It demonstrated similar rupture rates between the two groups (short arm splint: 4.4% after 1, 3, and 6 weeks; long arm splint: 3.9% after 1, 2, and 10 weeks) comparable to published levels using four-strand repair techniques and indicated that the use of a shorter splint appears to be safe for the rehabilitation of these injuries.

Full use of the hand for light activities and therapy to correct failures of finger extension begins only after 8 weeks, with heavy grasping activities being avoided for 12 weeks. Patients return to light manual activities at 8 -12 weeks and to heavy manual labour at 12 weeks after surgery. Although suggestions of shortening of the period of splinting are sometimes aired in meetings, they have not yet appeared in print. An interesting finding of the recent unpublished work in Bern/Switzerland (see below) was that the ruptures occurred later following multi-strand repairs (average rupture time 47(range 24-80) days) then reported previously with two-strand repairs, after which rupture commonly occurred in the first four weeks [9].

While this may reflect particular aspects of management in this unit, it nevertheless, should suggest caution moving to a shortened splinting period and suggests a need for further investigation.

Many of the recent papers described how active motion protocols aim to increase early tendon excursion to prevent adhesion formation and to produce increased motion [3-7].

Active/passive Rehabilitation protocols and functional outcome

One review analysis [3] showed that in passive motion rehabilitation, the overall complication rate was 13%, with 4% from rupture and 9% from decreased motion. Active motion rehabilitation showed an overall 11% complication rate, with 5% from ruptures and 6% from decreased motion. Rupture rate in early active motion articles did not reveal statistical difference between 4-strand, 2-strand or 6-strand repair. Overall, there was not a statistically significant difference when comparing total complications between passive versus active protocols. However, while passive protocols had a statistically significant lower risk of rupture, they also had a significantly higher risk of decreased post-operative range of motion compared to early active motion protocols.

Trumble et al [4], who produced level I evidence directly comparing active place-and-hold therapy with passive motion. The study showed greater interphalangeal joint motion, significantly smaller flexion contractures, and higher patient satisfaction with early active motion without increased risk for repair rupture. They reported a 3% rupture rate.

Fruhe et al [8] compared early passive mobilization (EPM) with controlled active motion (CAM) after a 4-strand flexor tendon repair in zones 1 and 2 in 159 digits. There was a statistically significant difference between the TAM values of the EPM (n=87, TAM 170°) and the CAM (n=14, TAM 200°) protocols 4 weeks after surgery but not at 12 weeks (TAM 220°). Rupture rates were 5% (CAM) and 7% (EPM), which were not statistically different.

More recently, there has been some question as to whether early, limited arc active motion might have some benefit over place and hold exercise, but this has not been studied formally. Of the ongoing rehabilitation controversies, possibly the one most often discussed is which is the best of the active mobilization techniques today: Kleinert (active extension-passive flexion), now often amalgamated with that of Dureau-Houser, or Early Active Mobilization (active extension-active flexion). If one looks at both techniques closely, one realizes that both are moving towards freer movement and both are pushing repairs ever harder during the early post-operative period, making this discussion an unproductive exercise. The questions begged by this trend to mobilise earlier and harder are how far we can go along this track without increasing the rate of tendon rupture and do we need to follow this path, rather than which is the best regimen for doing this. It also has to be borne in mind that many units repairing flexor tendons have insufficient therapists and are unlikely to acquire more in the current economic climate. Early active mobilisation is the cheapest and least therapist dependent method of rehabilitation. The papers published in this century increasingly report mobilisation by early active motion, which may reflect these economic benefits rather than any functional benefit.

SURGICAL CONSIDERATIONS

At the time of writing, there is no ‘best’ suture material or ‘best’ suture technique and the choice of each in any one unit, country or area of the world is more often determined by opinion, historical precedence and availability of particular materials than by science.

Number of strands, core suture techniques and functional outcome

The ‘best’ of core sutures still remains to be identified, with surgeons publishing their results during the last ten years following 4-strand or 6-strand core suture repair reporting an average of 5.4 (range 0-17%) repair ruptures. (Table 1) Critical analysis of the rupture rates in clinical papers written during the last twenty years fails to show a consistently significant reduction in rupture of repairs, despite the laboratory evidence that four and six strand suture techniques are stronger than two-strand repairs. Most reported series of primary flexor tendon repairs in zone 2 of the fingers, which has been the testing ground of flexor tendon surgery for fifty years, include a rupture rate of approximately 5%, whatever method of core and circumferential suturing is used.

A recent meta-analysis demonstrated no significant difference in rupture rates between 2-strand and multi-strand repairs. [6] This meta-analysis also showed a trend but no statistical significance that early active motion using a 4-strand core suture repair technique had a lower risk for rupture (2%) compared to those using a 2-strand technique (6%).

In another review [7], no difference in functional outcomes between 2- and multistrand core suture flexor tendon repairs could be shown. A comparison of 2-strand (755 digits vs 656 digits) versus multistrand (664 digits vs 145 digits) showed no significant difference in outcomes (Strickland Criteria group vs ASSH criteria group). The repair technique was also examined in zone 2 in the 2-strand repair group with modified Kessler (634 digits) versus other techniques (110 digits); no significant difference was found in either outcomes or rupture rate. There was a rupture rate of 3.9% (2-strand repair group: 4.3%, multistrand repair group: 3.2%). There was a trend for a lower rupture rate in the multistrand repair group but without statistical significance.

Even if rupture rates have slightly decreased over the last 10 years there remains great variation in results between different units, with some studies having higher rupture rates despite multistrand repair and other case series using two-strand sutures without any rupture. [8] (Table 1)

In a review by Elliot et al. [9] the rupture and re-repair rate was evaluated between 1989-2003. The decrease of the rupture rates has been seen to decrease in reports of more recent years, typically after 2005 but remained between 2-7%. [9] With increased repair strength, the rate of ruptures seem to occur later than in the review by Elliot. Our own experience (University Hospital Bern) in a recent unpublished series of 147 flexor tendon repairs between 2011-13 using a six strand repair and early active flexion protocol [10,11] with flexion of the wrist in 30° for 4 weeks demonstrated a surprisingly high rupture rate of 10%. The average of rupture time was at 46.7 days (24-80) after primary repair. (Table 2) In 3 patients, there was a history of a fall causing the rupture, 1 patient suffered from a connective tissue disease, while 6 times no rupture cause could be defined. In 6 cases the FDS tendon was resected (indicating perhaps a more difficult repair?). Eleven of the ruptured tendons had been treated with early active flexion protocol while 5 followed a classic Kleinert regime (active extension, passive flexion). Exceptionally, in 2 of 16 ruptures, a 4 strand and not a 6 strand repair was performed. This rupture rate is in contrast to another published series including 51 flexor tendon repairs with the same repair technique (6-strand Lim Tsai and epitendinous running suture) and an early active flexion protocol, which recorded a rupture rate of 2%. [10,11]

Unpublished recent data from Chelmsford also suggests no improvement in rupture rate despite a move towards four and six strand core sutures. There is also some evidence that suture material has a deleterious effect on tenocyte activity and, hence, a possibility that increasing amounts of suture material increase this effect [12]. So, perhaps we are, unwittingly, making tendon repair breakdown more likely as we put more foreign suture material into the tendon and simply putting in more complex sutures is possibly not the answer, or not the only answer. Inserting these more complicated sutures may have another cost: they are more difficult to insert and make an already complicated procedure even more so. Bearing in mind that most primary flexor tendon surgery is carried out by trainee hand surgeons worldwide, this may prove a serious disadvantage to their use. An alternative approach has become increasingly popular in the Far East using a single suture repair with a looped double strand nylon suture. Tang and his colleagues [13] still could not avoid the inevitable small rupture rate in their early clinical study, but its simplicity at a time when the Western approach may be becoming too complicated.

Over the past 10 years, surgeons have reported good to excellent results in 80% or more of the tendons that underwent 4-strand or 6-strand core suture repair, with 0% to 17% repair ruptures, on average 5.4%. (Table 1) This period saw the first widespread use of multi-strand core suture repairs, but in most reports disruption is still seen after 5 weeks during early active motion. There are reports of no repair ruptures in some case series, but, despite all of the progress in surgical technique and rehabilitation protocols, the rupture rate has not disappeared yet. (Table 1) Nevertheless, most repairs are probably done currently with four-strand core sutures, although the literature in the last ten years includes more papers using two strand than multistrand repairs.

The Circumferential Suture

In the latter years of the last century, the tendon repair was commonly completed using a continuous circumferential over-and-over suture, usually of 5/0 or 6/0 monofilament nylon or polypropylene. This was originally introduced to tuck in ragged parts of the tendon edges to allow easier gliding. This is particularly so along the deep surface of the tendon repair after completing the core suture, especially in the tight confines adjacent to the A4 pulley. Placing sutures along the ‘back wall’ of the repair prior to completing the core suture, a technique commonly used with simple circumferential suturing to avoid bunching of the repair, is very much more difficult with the complex circumferential sutures. Although elaboration of the circumferential suture raised the possibility of dispensing with the core suture entirely, the pendulum of clinical activity has swung back more recently to increasing the core suture strength, with simple circumferential over-and-over suturing being the commonest finishing suture in current use.

The Sheath

The period of closing the tendon sheath completely has passed. The repaired tendons, which are inevitably greater in diameter than the original tendon, are more likely to suffer restriction of their free movement if the sheath has been closed. However, even with a policy of simply laying the sheath back, catching of some repairs on the main pulleys remains a problem. Elliot [14] and Tang [13] have pointed out that repairs snagging on pulleys treated by early mobilisation will either restrict movement of the finger or cause the repair to snap and suggested that judicious venting of the A2 and A4 pulleys is often necessary to achieve free movement of the repair. This does not allow bow-stringing of the tendons provided most of the sheath is intact [8,9]. Wide-awake surgery [15] makes this factor more obvious to the operating surgeon. In all tendon surgery, surgeons should consider the diameters of the pulleys and how the tendon fits inside them. It is crucial to always leave room to accommodate edema and swelling of tendons that have been operated on. [7]

Improving the results of tendon repair by biological and biophysical interventions. Investigators have studied the effect of added lubricants on reducing adhesion formation for many years [17-29]. Results have been inconsistent, perhaps related to the residence time of the lubricant preparation. Higher molecular weight formulations appear to have better biological results in some studies, but not uniformly. Fixing a lubricant to the tendon surface has a large effect on reducing adhesions, but at the cost of delaying healing, at least in animal models. Adding stem cells within the repair site can to some extent reverse this problem, again in animal models, but there have been no clinical reports on the use of stem cells to aid flexor tendon healing [28].

CONCLUSIONS

Over the last 10 years, repair strength (4- and 6-strand repair) and newer suture materials (double loop polyester, supramid or tenofix) have been improved as well as active mobilization rehabilitation protocols including a change of wrist position by modification of splints to reduce the work of flexion during active flexion. Despite all of these modifications, tendon ruptures have not been eliminated, although they may seem to occur later, after 4-10 weeks, rather than at 2-4 weeks, as was often noted in past studies. This might suggest that the stronger repair may prevent earlier ruptures but raises the question as to whether stronger repairs and earlier mobilization may slow healing somehow, due either to the bulk of the multistrand repairs or to gapping that proceeds more slowly to rupture with a multistrand repair than it might with a 2-strand suture. The near future will show whether a change of wrist position and avoiding place and hold positions in the controlled active motion protocols will improve the results, or whether application of lubricants [29] will help to avoid gapping and rupturing of the tendons while maintaining full interphalangeal joint motion.
The central tenet of modern flexor tendon surgery is to repair and move divided flexor tendons within a few days of injury.

REFERENCES

REFERENCES OF TABLE 1

The principle of the core sutures was originally described in 1917 by Mason and Allen, showing that a six-strand suture which achieves a greater strength and increased tensile strength from the Halsted peripheral nerve. Savage (1988) suggested that the degree of flexion of the wrist in the splint is probably less significant than previously believed. In fact, the extreme flexion advocated in early papers is almost a Phalen test and can have the same effect on the median nerve as this test, particularly when associated with the considerable local oedema of a zone 5 injury. Savage (1988) suggested that flexion of the wrist did not achieve less tension on flexor tendons repaired distal to the wrist because any relaxation of the flexor muscles was counteracted by increased tension on, and spontaneous firing of, the extensor muscles applying force to the wrist in the opposite direction. He suggested that the position achieving least tension on repairs in the fingers and palm was the ‘resting position’ in which we commonly splint hands, with the wrist in slight extension.

He suggested that the position achieving least tension on repairs in the fingers and palm was the ‘resting position’ in which we commonly splint hands, with the wrist in slight extension.

The principle of the core sutures was originally described in 1917 by Mason and Allen, showing that a six-strand suture which achieves a greater strength and increased tensile strength from the Halsted peripheral nerve. Savage (1988) suggested that the degree of flexion of the wrist in the splint is probably less significant than previously believed. In fact, the extreme flexion advocated in early papers is almost a Phalen test and can have the same effect on the median nerve as this test, particularly when associated with the considerable local oedema of a zone 5 injury. Savage (1988) suggested that flexion of the wrist did not achieve less tension on flexor tendons repaired distal to the wrist because any relaxation of the flexor muscles was counteracted by increased tension on, and spontaneous firing of, the extensor muscles applying force to the wrist in the opposite direction. He suggested that the position achieving least tension on repairs in the fingers and palm was the ‘resting position’ in which we commonly splint hands, with the wrist in slight extension.

- The fundamental need to mobilise repaired flexor tendons early to avoid adhesion and loss of tendon gliding is now generally accepted, as is the fact that healing of the flexor tendon, at least in the digits, does not necessitate the formation of adhesions. Experimental evidence would also suggest that this early movement encourages more rapid tendon healing under the influence of longitudinal forces (Mason and Allen, 1941; Gelberman et al. 1981).

- Mobilising primary flexor tendon repairs completely passively in both directions (passive extension – passive flexion), either by a therapist or by the patient with his/her other hand, was introduced by Duran and Houser in 1975 and embraced by Strickland and his colleagues in Indianapolis (Strickland and Glogovac, 1980). Although the original authors had a 15% rupture rate and only 53% of the digits achieved a good or excellent range of motion in the second paper, this technique has been used widely, particularly in the United States.

- The series reported by Silfverskiöld and May, in 1994, from Gothenburg in Sweden, has probably the best results reported from a civilian unit, to date, in the world. It actually combines features of Kleiner, Duran-Houser and Belfast mobilizations.

Skin coverage in hand reconstruction is a challenging and vast chapter in Hand Surgery and to cover every aspect of it in a report is simply not feasible. Therefore this report focuses on a few specific topics. The coverage of anatomical districts like the fingertips is common ground for the Hand Surgeon worldwide, but in the last ten years different refinements have been published in order to optimize the reconstruction of this organ. Nevertheless, in many emergency departments the amputation of badly injured fingertips, including the thumb, remains the preferred treatment. The main focus of this report is to counter this tendency, providing alternatives to the surgeons. Large defects to the digits involving more than one segment, defects to the palm and to the dorsum of the hand are currently debated in international meetings. The use of skin substitutes vs. the use of extremely refined microsurgical procedures vs. classic island flaps is the basis of animated discussions, which are also influenced by cultural and socio economic factors around the world. This report offers the views of six different surgeons from four different countries, in the hope of animating discussions and to suggest new approaches.

FINGERTIP RECONSTRUCTION: THE ROLE OF CONSERVATIVE TREATMENT

SYLVIE CARMES AND CHRISTIAN DUMONTIER, FRANCE

As fingertip injuries are by far the most frequent injuries from emergency departments the most frequent finger injuries, one could expect that guidelines now exist to help emergency doctors as well as specialists to choose between treatment options. This is not yet the case. Treatment options in literature vary from the simplest conservative treatment to the most sophisticated microsurgical reconstruction. Regarding conservative treatment, some questions still arise:

WHAT DOES CONSERVATIVE TREATMENT MEAN?

In most publications, conservative treatment means lavage and debridement under local anaesthesia. Protrusive bone, if present, is removed by 2mm to 5mm under the level of soft-tissue. Dressings using paraffin tulle changed every two or three days has been extensively used with good results (Chow and How, 1982; Ilsen et al., 1987). However as the authors had often experienced difficulty in removing such dressings, which may damage the underlying granulation tissue, experiments have been made using bacitracine ointment (Lamon et al., 1983), Hyphecan (Hyphecan Care Limited, Kwai Chung, Hong Kong), polyurethane foam (Williamson et al., 1987), silver sulphadiazine (de Boer and Collinson, 1981; Riyat et al., 1997). In some series, dressing changes were made 2-4 times a day (Farrell et al., 1977).

As early as 1977 (Fox et al., 1977) occulsive dressings leaving a moist environment have also been proposed and Mennen (Mennen and Wiese, 1993) presented his experience in 1993 without debridement and the use of “Opsite” (Smith and Nephew Corporate, London, UK) changed only
Committee report

Authors insisted on the remodeled (6mm vs 3mm) in Lamon’s series. Series, or double compared to normal between 2.25mm and 4.1mm in Ryiat’s 1mm average in Ipsen’s series, it was discrimination was increased by normal in 50% to 80% of patients. Pulp sensitivity was considered (8%) were minor infections reported. Only in Lee’s series (3%) and Lamon’s Most series reported no infection. To heal than less severe injuries. According to the dressing protocol 3 to 12 weeks, with larger injuries and exposed bone taking a longer time to heal than less severe injuries. According to the dressing protocol 3 to 29 dressing changes were necessary. Accordingly return to work took from 2 to 60 days with an average of 20 days. Most series reported no infection. Only in Lee’s series (3%) and Lamon’s (8%) were minor infections reported. Pulp sensitivity was considered normal in 50% to 80% of patients. When measured, Weber’s two point discrimination was increased by 1mm average in Ipsen’s series, it was between 2.25mm and 4.1mm in Ryiat’s series, or double compared to normal (8mm vs 3mm) in Lamon’s series. Results were considered good to excellent in 90% to 100% of cases. Authors insisted on the remodelled “fingerprint” and barely visible scars, regular perspiration, and very limited disability. Pulp tenderness was present in about 20% of cases (Riyat et al., 1997; Ipsen et al., 1987) but was less frequent than with other methods. Pulp shortening or problems were few, while nail dystrophies were considered frequent, varying between 25% to 60% (Chow et al., 1982; Ipsen et al., 1987; Riyat et al., 1997). Only half of them were disabling. Nail dystrophies were reported in only 50% of cases if the injury is in the distal third of the sterile matrix (Chow et al., 1982).

Which type of conservative treatment is superior to the others? None has really proved superior. In Allen’s type I and II injuries (Fig 1 - below), dressing change was less painful in the silver sulphadiazine group compared to Paraffin, while at 3 weeks the fingertip was more sensitive. Healing was faster in the paraffin group, but shrinkage and shortening was also more evident (Riyat et al., 1997). It seems that occlusive dressing without initial debridement is simpler to use, results in more comfortable dressing, and dressing change. Occlusive dressings may result in less wound contraction and a more cosmetically acceptable outcome.

When should conservative treatment not be used? This is the major question. Particular emphasis is placed on involvement of distal phalangeal bone and nail matrix. However there is a high disparity in the literature that comes from variation in the injuries themselves with respect to orientation, tissue quality, vascularity, and patient factors such as age, hand use and occupation, smoking history, and concurrent diseases. What is obvious is that, when compared to other treatment modalities, conservative treatment is always favourable. Results of conservative treatment were superior to other types of treatment including flaps, with less pain and stiffness, less disability, faster healing time and fewer complications in Chow’s series of 200 cases. There were no differences in functional and aesthetic outcomes at one year follow up in Söderberg’s series. When comparing 7 types of treatment, simple dressings gave excellent results in Mä’s series (Mä et al., 1982). Recently, Van den Berg (Van den Berg et al., 2012) found that the outcome of treatment of Allen II, III, and IV fingertip injuries (Fig 1) was irrespective of the treatment chosen. From the literature it appears that bone exposure is not a major problem if the bone is not protruding. However, except for the most simple sterile nail matrix injuries, nail dystrophies will not be avoided with conservative treatment. Using Evans PNB classification (Table 1), Muneuchi (Muneuchi et al., 2009) found that the boundaries between surgical treatment and conservative treatment were PNB 386, 666 and 700.

David Elliot, UK

Perhaps the single most important and useful technique of digital reconstruction is the exploitation of the astonishing ability of the skin of the digits to close defects of considerable size by a combination of wound contraction and re-epithelialisation to give a cosmetic and functional result which cannot be bettered by any surgical procedure. This ability is well recognised and exploited in the management of digital tip injuries (Allen 1980, Chow and Ho 1982; Lee et al 1995; Mennen and Wiese 1993). In a moist environment, in the absence of infection, this occurs relatively quickly, not only at the tips but also on the other aspects of the digits. Galen recognised this almost two millennia ago and, two millennia before Galen, the Smith papyrus describes several hundred means of achieving healing of skin wounds by covering them with mixtures of honey and animal fats in ancient Egypt. Skin grafting of all defects of the digits has been a particular feature of plastic surgical management of hand injuries during the last fifty years which is often unnecessary and introduces further morbidity and delay of mobilisation. Healing open wounds under dressings avoids the creation of secondary donor sites and the patient can be encouraged to move if the bandaging is reduced to the minimum necessary to provide a moist environment for the raw area. The opportunity of dressing changes is used to encourage movement under water. This is both comfortable and helps debride the wounds. A further advantage of open wound management is that the oedema which is responsible for much of the long-term morbidity of digital injuries is not retained in the digit but leaks out of the open wound during early mobilisation. While the dogma of skin grafting has been dispelled for digital tip injuries without bone exposure, it is, unfortunately, still common practice in many hand surgery units to graft all skin defects of other parts of the digits. If skin can replace itself under moist antiseptic dressings, then operating to achieve skin cover, per se, is a dubious indication for surgery. However, we do require well-vascularised subcutaneous soft tissue to provide adequate protection of the bone at the digital tip, if exposed. With slight bone exposure, the bone may be nibbled back until it is covered by subcutaneous pulp tissue. The skin wound is then healed by secondary intention under moist antiseptic dressings. In doing this, we have accepted very slight digital

shortening in exchange for a simple plan of management. In most other circumstances, we are committed to moving flaps. In a ragged injury with significant bone exposure, there may be lengths of soft tissues adjacent to the amputation stump which are adequately vascularised and of sufficient size to provide bone cover; these “opportunistic flaps” can be used to convert the tip into a skin wound which can be healed by dressings (Fig 2). Where such opportunity for simple reconstruction of the digital tip does not exist, finger length can be maintained at that of the amputation by the use of flap reconstruction of the stump. Homodigital reconstruction involves rearrangement of the soft tissues of the injured digit to achieve healing without seeking tissue for reconstruction from outside that digit (Mouchet and Gilbert, 1982; Schiund et al., 1985; Foucher et al., 1989). While this concept of reconstruction has definite advantages of reconstructing ‘like with like’ and avoiding further scarring and morbidity elsewhere on the hand or body, the availability of donor tissue within an injured digit is obviously limited. Many of the injuries for which homodigital advancement flaps are used are palmar oblique with the amputation removing both skin and subcutaneous soft tissue distally to expose the bone but removing only skin proximally. We do not excise the pulp which is denuded of skin cover but use it as the leading edge of the advancement flap(s), so lengthening the flap and reducing the extent to which it must be advanced. This technique does not allow direct skin to nail approximation but achieves cover of the distal bone with soft tissue. The digital tip is, thus, converted into an injury which can be epithelialised under dressings. A secondary benefit of this method of advancing homodigital flaps is that the process of epithelialisation helps to round off the digital tips and improves their final appearance.

### THE TRAUMATIC NAIL COMPLEX

#### SYLVIE CARMES AND CHRISTIAN DUMONTIER, FRANCE

In this short report, we will only focus on acute nail complex injuries and will not discuss reconstruction or the treatment of associated phalangeal fractures. Since the publications of Zook and Shepard in the 80’s (Zook, 1981; Shepard, 1983), few publications have been presented regarding the high frequency of nail complex trauma. Most of them are technical tips that improve both the safety of the treatment and the quality of the functional as well as aesthetic results. Nail traumas represent 8% of all finger injuries in adults and 5% to 6% of child trauma (Duthie and Adams, 1984; Guy, 1990; Ardouin et al., 1997). The middle finger and thumb are the digits most frequently involved. A crushing mechanism is the most frequent cause of the lesion. In one personal series of almost 200 cases (Carmès et al. under submission), surgical exploration found: 47 isolated lesions of the nail plate (25%), 103 nail bed lesions (55%), 14 matrix (+/- bed) lesions and 23 nail bed hematomas (12.3%). In 134 cases (71.65%) there was an associated lesion: of the pulp in 50 cases (26.7%), of the distal phalanx in 29 cases (15.5%), an associated pulp and phalangeal lesion in 49 cases (26.2%) and another lesion of the finger or hand in 22 cases (11.8%). The associated lesion was on the same finger in 128 cases.

### SHOULD ALL NAIL TRAUMA BE TREATED?

Nail complex and fingertip injuries are frequently associated. Although conservative treatment usually gives good results for pulp injuries, nail dystrophies are always present (up to 60% of cases) except for the most minor injuries involving less than a third of the distal nail bed (Chow, 1982; Ipsen, 1987). Only half of them were disabling. We believe that nail injuries should be treated as a separate entity, whatever the treatment of associated lesions may be, as inadequate treatment may lead to severe disabling sequelae while early treatment usually gives good to excellent results (Ardouin et al., 1997; Inglefield et al., 1995; Shepard, 1990).

### NAIL PLATE INJURIES

Nail plate injuries are the less severe lesions and one should ask whether or not the nail plate should be replaced. O’Shaughnessy et al. found no difference whether or not the nail plate was replaced (O’Shaughnessy, 1990), however Zook recommended replacement and found that its non-replacement gave less satisfactory results (Zook et al., 1984). Recently, nail replacement in paediatric cases has been challenged and Miranda (2013) considered its replacement as more detrimental than absence of nail plate or substitute. We use sutures that do not pass through the nail complex but only pass through the lateral side of the pulp. Others do not fix the nail plate anymore and have found that the plate quickly adheres to the nail bed and will stay in place if the dressing is changed carefully (Tos, 2012).

If one chooses to replace the nail plate when absent or destroyed, among the many substitutes that have been proposed, we use, as do others (Tos et al., 2009), the bubble trap (reservoir) of a perfusion set, as the natural curvature is adapted to most nails. This substitute is sterile, inexpensive, and easily available in emergency and elective operating theatres. A small hole in its proximal part is made to allow for drainage.

### NAIL HAEMATOMAS

There are many discussions about the best treatment option for subungual nail haematomas (Mignemi et al., 2013). Only large subungual haematomas present with lesions that are amenable to repair (Simon and Wolgin, 1987) but surgical exploration is still questionable (Seaberg et al., 1991). We have chosen to explore those patients whose subungual hematomas were over 50% of the surface of the nail plate; this is a current trend today as the quality of nail edges is regarded as more important than the percentage of hematoma (Sommer and Brown, 2011).

Nail bed and/or matrix wounds Zook (1981, 1984) and Shepard (1983, 1990) emphasized the need for meticulous repair using loops and small sutures (6/0 or under). To get access to the underlying tissue, removal of the nail plate is mandatory. Partial removal can be done for nail tumor surgery but is not indicated in trauma cases. To get access to the nail matrix, surgical incision at the junction of the proximal and lateral nail wall, as described by Kanavel, is necessary. One of the incisions can be prolonged over the second phalanx if a rotation-advancement flap is needed to reconstruct the proximal nail wall. Large debridement is not necessary due to the good vascularization of the tissues and approximation sutures are all that is needed as the nail bed or matrix do not glide over the distal phalanx. All nail bed/ matrix fragments are preserved and released as free grafts in order to attain an optimal final result. Any irregularities of the wound edges of the nail bed or matrix should be avoided. We believe that moulding the repair using the nail plate or a substitute is a useful adjunct. We have no experience with the use of cyanoacrylate for the repair of nail bed wounds.

### NAIL FOLD RECONSTRUCTION

Nail fold integrity is needed in order to have a normal nail shape. Reconstruction is made using local flaps, most of them being designed for burn injuries. However in distal finger amputation, the nail is shortened and this is sometimes badly
The use of skin substitutes vs. the use of extremely refined microsurgical procedures vs. classic island flaps is the basis of animated discussions, which are also influenced by cultural and socio-economic factors around the world.
THE SEGmüLLER FLAP
Homodigital advancement flaps are of particular value in respect of their ability to replace the missing fingertip after amputation with similar and innervated soft tissues, while retaining digital length at, or near to, that of the level of amputation. The lateral V-Y flap, based on the small vessels of the distal digital pulp tissue, was first described as a unilateral flap by Geissendorfer (1943) and, later, used as bilateral flaps by Kutler (1947) and others.

The Geissendorfer/Kutler flap was designed as a triangle on the lateral aspect of the distal segment of the finger with the apex of the triangle proximal and the flap raised on the microcirculation of the subcutaneous pulp tissue beyond the trifurcation of the neurovascular bundle. It continues to be described in most textbooks and continues to disappoint with its failure to advance as much as shown in line drawings. The minor modification described by Shephard (1983) is only a little better. A larger, but less well known, lateral V-Y flap, with the apex taken back to the DIP joint crease and islanded on the neurovascular bundle was first described in Switzerland by Segmüller (Segmüller, 1976) and again, independently in South Africa, by Buddulph (1979). This flap is more useful, being more mobile and capable of greater advancement. However, these flaps remain confined to the terminal segment of the finger, so still have limited potential for advancement. Lanzetta et al (1995) reported the use of longer Segmüller flaps in 5 cases with good results. Independently, over the same period, we also developed flaps based on the Segmüller principle, but extending proximally into the middle and, even, into the proximal segment of the digit, to achieve larger flaps which are capable of greater advancement and, so, greater versatility (Smith and Elliot, 2000). The extended version of the flap is of particular use in the treatment of extensive volar-sloping defects of the tips of the digits for which the shorter bipedicile flaps are not appropriate. The latter paper analyses the results of 100 such flaps, but without raising the V-Y tail, with skin graft reconstruction of the proximal donor defect, with similar results (Schindl et al., 1975; Foucher and al., 1989).

The extended version of the Segmüller flap involves the use of a larger triangular flap, also raised as an island on the neurovascular pedicle, but with the apex of the flap at the PIP crease. The base of the flap is the proximal margin of the tip defect and the lateral boundary is the mid-lateral line of the finger. The third side of the flap is marked to join the flap apex (proximally) to the base of the flap in the mid-line of the finger. The flap extends only to the midline of the finger and differs in this respect from a Venkataswami flap (Venkataswami and Subramanian, 2000), which is taken right across the volar aspect of the finger to the other mid-lateral line and, at least theoretically, has no innervation distally on the side opposite the neurovascular bundle on which it is raised.

Because of the volar sloping nature of the tip injuries for which these flaps are commonly used, the proximal edge of the tip defect often includes several millimetres of subcutaneous tissue without skin. This is included in the flap to increase its length and reduce the distance by which it must be advanced to the end of the digit, with the consequence that the bone at the tip of the finger may only be covered by denuded pulp tissue after flap advancement and not by pulp and skin. When this is the case, the tip is treated with moist antiseptic dressings for several weeks until re-epithelialisation completes tip cover. The flap is then advanced without tension and loosely sutured to cover the bone of the digit tip. Commonly, part of the mid-lateral margin of the flap is left unsutured to avoid tension from post-operative oedema. This wound subsequently heals by secondary epithelialisation under moist antiseptic dressings. A single flap is usually raised on the blind side of the finger, unless the particular shape of the tip defect determines otherwise. In some injuries, a single flap provides sufficient tissue to reconstruct the digital tip but, in others, two flaps are necessary and a second flap is raised on the other neurovascular bundle and advanced (Fig 3). The finger is splinted dorsally with the PIP joint slightly flexed for the first 72 hours to take tension off the pedicle. However, this position is not maintained beyond this length of time as there is a risk of volar plate contracture of the PIP joint following use of all of the longer advancement flaps. After 72 hours, specific measures are taken by the therapists to avoid this, extension exercises and/or splinting sometimes being necessary for several weeks or, occasionally, months.

Commendable features of the extended Segmüller flap are its versatility, ease of use and reliability. It is a single stage reconstruction which borrows from no other part than the already injured recipient digit. While requiring careful technique, it requires no microsurgical expertise and is well within the capabilities of most hand surgeons. It can be used to treat digital tip defects of variable size, shape and slope. The flap is suitable for any transverse or oblique loss of the distal segment, however steeply sloping the latter, with the length of the flap being tailored to the size of the tissue loss. Where one flap provides insufficient tissue bulk at the tip after advancement, a second can be brought into use. Like all homodigital flaps, this flap is useful in multidigital injuries in which adjacent digits are not available as a source of flaps. It can also be moved dorsally to reconstruct the bone.

COMMITTEE REPORT www.ifssh.info NOVEMBER2015 COMMITTEE REPORT
nailbed loss or, in combination with other flaps, for more complex reconstruction of combined tip and dorsal injuries.

THOMAS GIESEN, MAURIZIO CALCAGNI, SWITZERLAND

The role of perforator flaps and free flaps for the reconstruction of fingertips.

Recent publications have widened the choice of flaps in fingertip reconstruction, raising the technical difficulty of surgical reconstruction with the aim of lowering the local morbidity related to local flaps and at the same time to improve the quality of reconstruction.

Koshima et al., recently published the use of perforator flaps to reconstruct the tip of the finger (Koshima et al., 2006, Mitsunaga et al., 2010). These flaps are based on the small perforator arteries rising from the digital artery at the middle phalanx level, allowing the coverage of the fingertip without the need to sacrifice a digital artery as in homodigital reverse flaps. In our practice these flaps have not so far found any practical application, as for the classic local flaps, the Venkataswami flap or the Segmüller flap, which offer, with a simpler technique, an equivalent skin quality that is, in contrast, immediately sensate. In our opinion there is no relevant difference in the donor site and the latter flaps are technically less demanding.

The use of free flaps for reconstruction of the fingertip has, in our practice, very limited indications. We normally return to these flaps in acute traumatic cases of volar oblique amputations if there is a major contraindication or the impossibility of using an adjacent digit. Our indication for free flaps is if there is the need to reconstruct pulp in a “cold” situation where the soft tissue cover of the fingertip is insufficient and the other digits are intact. In those situations our first choice is a free venous flap harvested from the palmar aspect of the wrist, including skin from the thenar eminence or hypothenar eminence and the terminal branches of the lateral or medial cutaneous nerve of the forearm. We take two parallel veins from the proximal margin of the flap, using one of them as an afferent vessel anastomosed to a digital artery and one of them as a draining vein anastomosed preferentially to a volar vein of the digit, if available (Fig 4).

The skin of these flaps is similar to the skin of the pulp and the harvesting of these flaps is technically easy. We have very limited experience of the use of free thenar flaps and their modifications (Yang et al., 2010) based on the palmar branch of the radial artery and including terminal branches of the cutaneous nerves of the distal forearm and of the proximal hand. The reliability of these flaps was questionable and the harvesting more demanding; therefore we abandoned this technique.

In cases of small defects to the pulp we prefer the hemipulp free flap from the second toe (Kimura and Saito, 2006). In cases of composite defects including bone we prefer composite flaps from the great toe.

LARGE DEFECTS TO THE DIGITS

ROBERTO ADANI, ITALY

Refrinements of the heterodigital island flap

The heterodigital flap comes from the standard cross-finger flap (Gourdin and Pangman, 1950), which is considered a random pattern regional flap employing the dorsal skin of an adjacent finger to provide soft tissue coverage to resurface a volar finger defect including pulp loss. To achieve recovery of sensitivity, the dorsal digital nerves (one or both) are included and sutured to the digital nerves of the injured finger (Lassner et al., 2002; Shao et al., 2009). There are two main disadvantages related to this technique: it is a two-stage procedure, and it requires finger immobilisation for up to three weeks. The heterodigital arterialized flap represents an evolution of the above methods: it is transferred from the lateral surface of a nearby digit including only the digital artery without the digital nerve. To reduce donor site morbidity the flap is harvested from the lateral side of the middle phalanx with the vascular pedicle located on the palmar side of the flap (Hirase et al., 1992; Leupin et al., 1997). The cosmetic result of the grafted donor area is more acceptable because the defect is over the midlateral line without affecting the palmar aspect of the finger. Moreover the dorsal branch of the digital nerve raising from the main nerve at this level can be used to innervate the flap with acceptable sensory recovery (Adani et al., 2010).

With large skin digital pulp defects of the middle finger it is not always easy to resurface the pulp without extending the distal incision of the flap over the DIP joint crease on the donor finger. This may damage the function and the cosmetic appearance of the donor finger pulp. The heterodigital island flap with reverse-flow vascularisation (Adani et al., 1999; Adani et al., 2005) may answer such a problem. With this flap the pedicle is isolated up to its bifurcation in the palm and the common digital artery between the injured finger and the flap-donor finger is ligated just before its bifurcation. The Y-like vascular bifurcation then turns into a V shape and the two converging branches of the digital arteries become a single vascular pedicle for the flap, increasing its original length. The vascularization is supplied by a reversed flow through the proximal transverse digital palmar arch of the injured finger allowing the flap to cover the defect completely. The heterodigital flap achieves acceptable sensory recovery: the mean static two-point discrimination test (s2PD) over the reconstructed pulp is about 9mm and the mean dynamic two-point discrimination test (m2PD) 7mm (Adani et al., 1999, Adani et al., 2005). These results are very similar to those reported by other authors (Hirase et al., 1992; Leupin et al., 1997) using the same donor area. No sensory deficit was reported in the donor fingers with the direct and the reverse heterodigital pedicle flaps.

The heterodigital neurovascular island flap is indicated for large losses of finger pulp when a direct island flap could be too small to cover the defect and represents a suitable option instead of the reverse homodigital island flap or free flaps (Fig 5). The reverse-flow type may be employed for large loss of pulp to the index and middle finger. This procedure is not recommended in cases of severe crushing injury involving multiple finger pulp losses because of the...
possible damage to the vascular network including the proximal or middle transverse digital palmar arches.

THOMAS GIESEN AND MAURIZIO CALCAGNI, ITALY

Retrograde arterialized free venous flaps
Although the literature is encouraging with regard to the survival rate of arterialized free venous flaps, previously reported encouraging with regard to the middle transverse digital palmar network including the proximal or middle transverse digital palmar arches.

Figure 6: (A) two segment defect to the P1 and distal metacarpal of the dorsum of a replanted thumb. (B) Plan of a retrograde free venous flap from the dorsum of the foot in a obese patient. (C) Result at three months and (D) donor site at three months.

The position of the flap that is going to be arterialized with the feeding and the draining vessel and ligate it with a clip, as described by Lin (Lin et al., 2010).

In the literature, several papers have been published recently with refinements in this technique and the use of different donor sites like the dorsum of the foot (Yu et al., 2012), introducing the idea of the possibility for these flaps to become routine procedures in hand reconstruction.

LARGE DEFECTS OF THE HAND
ROBERTO ADANI, ITALY

The role of the ALT in the coverage of large defects in the hand, the palm and the dorsum
Fasciocutaneous flaps are most frequently used to cover hand defects (Saint-Cyr and Gupta, 2007).

Many factors should be considered when choosing a flap. The most significant are the cosmetic match of the skin surrounding the defect, the donor site morbidity and the simultaneous approach to wound debridement and flap harvesting (Scheker and Ahmed, 2007). In the last decade the anterolateral thigh flap has received considerable interest (Javaid and Cormack, 2003; Adani et al., 2005; Adani et al., 2006) from hand surgeons and particular interest (Javaid and Cormack, 2003; Adani et al., 2005; Adani et al., 2006) from hand surgeons and represents a good alternative to other fasciocutaneous flaps. The anterolateral thigh flap shows several advantages: simultaneous flap elevation and preparation; shorter operative time; longer vascular pedicle (approximately 10cm long); larger skin paddle. Despite its versatility, the anterolateral thigh flap has some potential drawbacks: the greatest concern has been variability of the perforators and flap reliability (Wang et al., 2005). Large clinical series show that almost all patients will have an adequate vessel for supplying the flap and Doppler examination can accurately identify the perforators preoperatively, planning the flap accurately. The flap should be thinned to approximately 3mm to 4mm by removing a considerable amount of fatty tissue before it is transferred onto the hand. This allows an optimal match between the donor tissue and the area to be reconstructed with the flap. Despite flap thinning, additional debulking could still be necessary to improve the final cosmetic result, particularly in Caucasian patients whose thigh characteristics differ from patients of Asian origin. Defects of the donor site smaller than 7cm - 8cm in width can be closed primarily without a skin graft. In this case the scar is less noticeable than with other flaps harvested from the arm or forearm. The donor site scars associated with skin grafts of larger defects may preclude its use, particularly in female patients. The ALT flap is recommended in very large defects of the dorsum of the hand and the wrist; if employed for palm reconstruction, it requires aggressive thinning and a secondary debulking to reach an acceptable appearance.
The current role of the forearm flap for reconstruction of the palm and dorsal hand

The radial forearm flap may be used to cover the dorsal aspect of the hand. The sacrifice of a major artery in an already traumatized hand and the donor site result, which is not always satisfactory, represent the major drawbacks of this surgical procedure. However if this flap can resurface medium-sized defects with direct closure of the donor site and without jeopardizing the vascularisation of the hand, this approach may still be useful in the armamentarium of hand surgeons. In our practice the radial forearm flap is mainly used with direct closure of the donor area avoiding the need for skin graft. These problems can be partially solved by the radial artery perforator flap used as either a fasciocutaneous flap or an adipofascial flap (Page and Chang, 2006; Ho and Chang, 2010; Saint-Cyr et al., 2010). The retrograde radial fascia-fat forearm flap removes only the fascia and fat layers of the forearm tissue leaving the radial artery and the forearm skin intact. The perforator flaps show some disadvantages: the pedicle is relatively bulky after rotation, which makes direct closure difficult, and their pivot point is located more proximally than in the traditional radial forearm flap making it difficult to extend and cover the distal dorsal aspect of the hand completely. For these reasons they can be used only to treat moderate-sized defects and they should be considered very carefully in patients with complex hand injuries to the forearm with possible damage to the perforators of the radial artery. Another possibility is to divide the radial forearm flap into different sections, following the perforators, by using a long narrow flap which allows primary closure of the donor site (Mateev et al., 2009). The use of the radial forearm flap with large skin defects (more than 20cm²) is more restricted because of the poor donor site result. Attempts to minimize the donor site morbidity have been widely reported in literature using different types of skin grafts (Zuidam et al., 2005; Ito et al., 2005), regional advancement flaps (Ahn et al., 2007; Lane et al., 2013) or special types of skin substitutes (Rowe et al., 2006; Murray et al., 2011). The radial forearm flap finds a specific indication for use in the anatomic region because it provides thin and pliable skin; on the contrary, it is not ideal for the hypothenar and central region of the palm, where stability cannot be achieved with this type of flap.

An evidence-based approach to conservative management of CMC OA

Anne Wajon, PhD

Pain at the base of the thumb is particularly common in postmenopausal women in the fifth to seventh decades of life (Swigart, Eaton, Glickel, & Johnson, 1999). It is frequently located either at the palmar surface of the trapeziometacarpal joint, or more dorsally, between the base of the first and second metacarpals. The pain is most often aggravated by opening jars, writing, turning taps and sustained grasp activities, however, in cases of more advanced arthritis, it can also result in a constant dull aching pain.

Radiographs may reveal joint space narrowing, sclerosis, articular debris and joint subluxation (Eaton & Glickel, 1999). It is particularly common in postmenopausal women in the fifth to seventh decades of life (Swigart, Eaton, Glickel, & Johnson, 1999). It is frequently located either at the palmar surface of the trapeziometacarpal joint, or more dorsally, between the base of the first and second metacarpals. The pain is most often aggravated by opening jars, writing, turning taps and sustained grasp activities, however, in cases of more advanced arthritis, it can also result in a constant dull aching pain.

Careful palpation of the STT joint and trapeziun, just distal to the scaphoid, will assist in determining the source of symptoms (Skirven, 1996). Further, axial compression and rotation of the first metacarpal on a stabilized trapezium (the grind test; Figure 1) is a recommended maneuver for reproducing pain and crepitus at the joint (Skirven, 1996).

Figure 1: The Grind test

It is important to provide the patient with pain at the base of the thumb education regarding the disease, including the diagnosis, likely prognosis, specific objectives of treatment, self-management approaches and instruction in joint protection techniques. It is essential for the patient to become aware of the activities that aggravate their symptoms, so they can understand the need to change their task performance by either using a different posture or technique, assistive devices or splints. By so doing, they will take some responsibility for alleviating their symptoms, and play an active role in their rehabilitation. Simple strategies include advice to:

- Use the strongest joint for the task
- Use two hands to hold a book or a stack of plates, to distribute the load
- Avoid prolonged static positions, such as holding a smart phone while texting with the other hand
- Alternate repetitive activities with rest breaks

Various assistive devices are available that assist patients perform ADL without aggravating their symptoms. They include jar openers, tap turners, large handled cutlery, large key holders, and wide-grip vegetable peelers. By identifying aggravating activities, patients will be able to identify which of these assistive techniques are best avoided.
devices could be useful in their day-to-day life.

Many patients find symptomatic relief with massage using Arnica or NSAIDs, and the regular use of thermal modalities. My recommendation for the patient who complains of morning stiffness is to gently squeeze a sponge in warm water on waking. Similarly, a hot pack at the end of the day can be helpful, although some people prefer to use cold after a period of overuse.

Figure 2: Neoprene thumb and wrist brace (eg Comfort Cool® from NCM)

Figure 3: Short opponens splint

A variety of splinting options are available for patients with pain at the base of the thumb, however there is no evidence to support the superiority of one over another (Wajon & Ada, 2005). Splints aim to relieve pain, prevent progression of deformity, reduce inflammation and provide support to allow improved function. In general, a more flexible neoprene style splint is appropriate for those with mild symptoms (Figure 2), and the rigid thermoplastic short opponens splint useful for those with more severe pain that limits most activities of daily living (Figure 3). The long opponens splint will be helpful for those with STT joint involvement as it supports the wrist (Figure 4), whereas the short opponens splint should suffice if the pain is limited to the carpometacarpal joint. Alternatively, the smaller Push Ortho CMC brace (Figure 5) (J. Colditz, 2000) or three point strap splint (Figure 6) (Wajon, 2000) may be useful for more specific task performance activities, including writing, stringed instrument playing and crafts. It is essential to consider the severity and source of symptoms, along with specific patient requirements when deciding which splint to provide.

While there is no evidence to support the superiority of one exercise program over another, there is a general consensus that exercise may improve pain, function and strength (Davenport, Jansen, & Yeandle, 2012; Wajon & Ada, 2009). Guidelines for the performance of exercises may be found in a narrative review by Valdes and Heyde (Valdes K & Von der Heyde, 2012). They suggest that exercises should be pain-free and not lead to an aggravation of pain for more than two hours after the activity. A retrospective review of a dynamic stability approach to the treatment of this common condition reported a reduction in pain and disability scores with a combination of splinting, web space release, mobilizations to provide distraction and to reduce dorsal subluxation, 1st dorsal interosseous strengthening and taping (O’Brien & Giveans, 2013).

Figure 4: Long opponens splint

Anatomical studies have identified the presence of mechanoreceptors in the dorsal carpometacarpal joint ligaments (Hagert & Mobargha, 2012), supporting their proprioceptive role in enhancing joint stability. Further, recent studies have confirmed the importance of the first dorsal interosseous in counteracting dorsal subluxation (Mobargha et al., 2015). This has led the author to develop specific exercises for neuromuscular retraining, particularly concentrating on activities that address stability. These exercises include improving the patient’s awareness and control of the alignment of their thumb while tracing along the line of a tennis ball with the tip of the thumb (Figure 7). Similarly, they may practice tearing sheets of paper while “maintaining the thumb joints in an ideal arc” (Figure 8) (J. C. Colditz, 2013), incorporate regular use of chopsticks to improve joint position sense and neuromuscular control (Figure 10), or enhance stability by rotating a credit card in exercise putty.

Considering the dorsal CMC joint capsule is innervated by the dorsal sensory branch of the radial nerve, and the volar capsule intermittently receives branches from the median nerve (Hagert E, 2012; Mobargha, Ludwig, Ladd, & Hagert, 2014), the author also instructs patients in radial (Figure 10) and/or median nerve glides (Figure 11). These exercises are particularly useful when patients report dorsal or volar CMC joint pain respectively, and have found to be effective in reducing pain sensitivity and increasing pinch strength (Villafane, Silva, Bishop, & Fernandez-Camero, 2012).

The specific intervention that is appropriate for any given patient will depend on the severity of the patient’s symptoms at the time, and their response to treatment provided. Failure of symptom relief with such conservative interventions may lead the therapist to consider whether graded motor imagery could be useful, as recent research has suggested sensitization mechanisms may contribute to chronic pain in this population (Chiarotto, Fernandez-de-Las-Penas, Castaldo, & Villafane, 2013). Of course, there will be some patients who fail to respond to conservative measures and decide to proceed with surgery for ongoing debilitating pain and limitation of function.

This article has been expanded from a recent short article written by this author in Grieve’s Modern Musculoskeletal Physiotherapy, 4th edition (2015).

**Member Society Updates**

**THE EGYPTIAN SOCIETY FOR SURGERY OF THE HAND AND MICROSURGERY (ESSHM)**
The Egyptian Society for Surgery of the Hand and Microsurgery has had a busy year in 2014-2015.

In October 2014, the annual Wrist Surgery Instructional Course was held in beautiful Alexandria under the leadership of Professor Esmam El Kairef, ESSHM President, and Professor Hany Morsey. The course was very successful and well attended.

In April 2015, the 8th annual congress of ESSHM was held in Cairo. The distinguished guest speakers included Professor Marc Garcia-Elias from Barcelona, Spain; Professor Jin Bo Tang from Nantong, China; and Professor Loree Killiainen from St. Paul, Minnesota, USA. The congress was also very well attended. Professor Garcia-Elias chaired an instructional course, along with Professor Nash Naam, on Wrist Examination and Evaluation. This was very popular.

Professor Tang chaired a hands-on surgical workshop, along with Professor Mostafa Mahmoud, on how to repair flexor tendons. These courses were the highlights of the meeting considering the talent and the quality of the course instructors.

The society still promotes local meetings in civilian and Military hospitals to promote hand surgery across the country. ESSHM continues to be the leader in the Arab World promoting hand surgery and research across the area and the Kuwaiti Hand Society has been accepted as a member of IFSSH during the last council meeting in Seattle, USA. The ESSHM has been accepted as a corresponding member of the European Federation of Societies for Microsurgery (EFSM).

This month (October) the annual Wrist Surgery Instructional Course will be held again in Alexandria. Professor Marc Garcia-Elias will be the distinguished guest speaker.

The 9th annual congress for ESSHM will be held in Cairo on April 5-7, 2016. We would like to invite all our friends from across the globe to honor us with their presence. The meeting will have a stimulating scientific program and an ambitious social program as well.

For information please email Professor Abdel Hakim A. Massoud at mass321@hotmail.com

**THE FINNISH SOCIETY FOR SURGERY OF THE HAND**
The Finnish Society for Surgery of the Hand is arranging the 2016 Scandinavian Hand Society meeting in Levi, Lapland, Finland. This will be held from 31 March to 3 April, 2016.

The topics of the meeting will include sports-related injuries of the elbow and the wrist, nerve and tendon transfers, brachial plexus surgery and new techniques in hand surgery. The speakers will be international top specialists as well as Scandinavian leading authors.

Full details are available on the website: www.sssh2016.fi

**FRENCH SOCIETY FOR SURGERY OF THE HAND (SFCM)**
Hand Surgery in France has probably never been so active than during 2015 regarding meetings and relationships with colleagues of other national Hand Surgery Societies.

First of all, the French Society for Hand Surgery gave up its old informal name (GEM, Groupe d’Etude de la Main) in January 2015, to become the SFCM, Société Française de Chirurgie de la Main (translation: French Society for Hand Surgery). The SFCM currently has more than 600 Members and has two meetings a year, the largest being the December meeting in Paris (about 1000 attendees each year). A junior members section was created in 2014 for residents and young fellows interested in hand surgery, and who are working in accredited hand and upper extremity surgical centers. We think this will be an incentive to produce excellent future hand surgeon. The SFCM has its own journal, "Chirurgie de la Main", a website (sfcm.fr) and a dedicated, highly efficient Secretary, Mrs. Juliette Chort.

The upcoming 2015 SFCM Meeting in Paris, to be held over three days in December, promises to be very special. The SFCM executive committee has invited two well-known international hand surgeons, Dr RA Berger (Rochester, Mayo Clinic, USA) and Dr D Slutsky (Los Angeles, USA), as well as a special Chinese Delegation convened by PC Ho (Hong Kong) which will include 10 well renowned surgeons from Mainland China (W Xu, CY Fan from Shanghai, SL Chen, B Liu from Beijing, JB Tang, YJ Rui from Jiangsu), from Hong Kong (PC Ho, CW Wong) and from Taiwan (JT Shih, YK Tu). All of these prestigious speakers will give lectures and will participate as session moderators. Two other highlights of the meeting will be the gala dinner at Palais du Luxembourg in Paris, a political and historical French bastion, and a lecture by Colonel Velluz, the former squadron leader of the French forces in Afghanistan.

Please join us for science and fun!
MEMBER SOCIETY UPDATES

the famous Patrouille de France flight escadrille. For the first time ever, the whole meeting will go all-electronic and will include a downloadable app. Since we should not forget our precious, highly qualified OR nurses, a special Nurses’ Session will also be a new feature on the Program this year. The heritage of the old “GEM” Pioneers is in good shape! The SFCM liaises in close relationship with other societies, such as the French Orthopedic Society and the French Plastic Surgery Society. This year for the very first time we will have a combined session within the Annual Orthopedic Meeting during their Specialty day on 11 November 2015. We have worked hard throughout this year to reinforce the links with both the French Orthopedic and Plastic Societies. The SFCM also has close ties with the GAM (Group for Microsurgery Advances- annual meeting in May), the GEMMSOR (Hand Physiotherapists Society- annual meeting in December in conjunction with SFCM meeting), the FESUM (European Federation for Emergency care of Hand Trauma- two annual meetings) and EWAS (European Wrist Arthroscopy Society which held no less than 3 hands-on meetings this year).

Twice a year, the EWAS sponsors a very special international “Wrist Arthroscopy Tour de France” where senior residents and fellows can watch prominent wrist arthroscopy surgeons perform numerous live arthroscopic procedures. Since 2005, EWAS has also sponsored an annual International Wrist Course in Lyon (alcoms69.fr) in October. This year, we will welcome 33 prestigious speakers from Europe, USA, Hong Kong, Japan and Australia.

I had the privilege of being the President of SFCM during this active and exciting year, and will also have the honor next year to participate in the Buenos Aires IFSSH Congress as President of the EWAS.

My thanks to the Editor of this Ezine.

Guillaume Herzberg
2015 President of SFCM (French Society for Hand Surgery)

GERMAN SOCIETY FOR SURGERY OF THE HAND (DGH)

During 2015, the German Society for Surgery of the Hand (DGH) council met several times to discuss further activities. The work on the hand trauma register was continued and new ideas were raised. Relationships with the German Society for Surgery (DGCH), the German Society for Plastic, Reconstructive and Aesthetic Surgery (DGPRÄC) as well as the German Society for Traumatology (DGU) and Orthopedic Surgery (DGOC) have been intensified with activities during several meetings.

The 56th annual congress of the DGH was held recently - September 22-24, 2015 in Bad Neustadt, Germany. Apparently, new ideas were raised. Relationships with the German Society for Surgery (DGCH), the German Society for Plastic, Reconstructive, and Aesthetic Surgery (DGPRÄC) as well as the German Society for Traumatology (DGU) and Orthopedic Surgery (DGOC) have been intensified with activities during several meetings.

The 56th annual congress of the DGH was held recently - September 22-24, 2015 in Bad Neustadt, Germany, in conjunction with the German Hand Therapist Group (DAHTH). Prof. Max Haerle was the President of the congress. He is also Secretary General of the Federation of European Societies for Surgery of the Hand (FESSH). The congress was very successful and the guest society was the Italian Society for Surgery of the Hand (SICM). New and old friendships have been fostered. The speaker for the traditional Buck-Gramcko Lecture of our society was Prof. Giorgio Brunelli from Brescia, Italy. The new President of the DGH is now Dr. Martin Richter from Bonn, Germany, and the new Secretary General is Prof. Jörg van Schoonhoven from Bad Neustadt, Germany.

2016 will be a busy year for the Germany Society. It will start with an invitation to be the guest society during the annual meeting of the American Association for Hand Surgery (AAHS) in Scottsdale, Arizona, USA, January 15-16. After this meeting, the council will focus on the next congress of the International Societies for Surgery of the Hand (IFSSH) from October 24-28, 2016 in Buenos Aires, Argentina. As the German Society for Surgery of the Hand (DGH) will host the following IFSSH triennial congress in May 2019 in Berlin, Germany, many DGH members have made travel plans to go to Argentina and support our friends over there.

The next annual congress of the German Society for Surgery of the Hand will be held in Frankfurt am Main, Germany, September 22-24, 2016. The American Association for Hand Surgery (AAHS) will be the invited guest society. Prof. Michael Sauerbier will be the local host and congress President, and the program co-chairs will be Prof. Riccardo Giunta (Munich, Germany) and Michael Neumeister (Springfield, Ill, USA). Scientific topics will include Microsurgical reconstruction after severe hand injuries; Thumb reconstruction; Treatment of malignant tumors of the hand and forearm; Scaphoid fractures and their sequelae; Dorsal radioulnar joint; and an open choice of subjects. The abstract submission deadline is May 8, 2016. Further information is available on the website: www.dgh-kongress.de

Michael Sauerbier, MD, PhD
IFSSH Delegate, German Society for Surgery of the Hand (DGH)

INDIAN SOCIETY FOR SURGERY OF THE HAND.

The 39th Annual Meeting of the Indian Society for Surgery of the Hand was held from 25th to 27th September, 2015 at Indore in the State of Madhya Pradesh. Indore is in central India and this was the first time this meeting was held in the city, keeping with the ideology of the ISSH to rotate the meetings to new places and also to propagate the spread of the specialty. Dr. Shailesh Gupta and Dr. Bhangani were the organizers and they did a creditable job.

The Indian Society for Surgery of the Hand had two guest orations - Prof. P C Ho (Hong Kong) delivered the BB Joshi Oration and Prof. Fuminori Kanaya delivered the Venkataswami Oration. Dr. Makarand Tare and Dr. Amit Tolat from the UK conducted a symposium on Flexor Tendon Injuries.

There was a change of the Secretary of the ISSH. The new address of the

Institute of Wrist Surgery, Lyon, France, during the Lyon Wrist Surgery 2011.

From left to right: M. Haerle, M. Boeckstyns, L. De Smet, P.C. Ho, C. Mathoulin, G. Herzberg, R. Luchetti, P. Liverneaux, D. Sulitsky, J.R. Haugstvedt, M. Chammas

Prof. Max Haerle (DGH Congress President in Ludwigsburg 2015) and Prof. Michael Sauerbier (DGH Congress President 2016 in Frankfurt am Main)

Buck-Gramcko Lecturer Prof. Giorgio Brunelli (third from left) with Prof. Riccardo Giunta, Prof. Max Haerle, Dr. Martin Richter
Secretary is as follows:

Dr. S. Raja Sabapathy continues to act as the liaison for the IFSSH and he has been elevated to be a member of the Board of Trustees of ISSH.

The next meeting of the ISSH will be held in Ranchi from 15th to 17th September, 2016. Dr Anant Sinha (Devkamal Hospital, Ranchi) will be the Organising Chairman.

Dr. Prakash Kotwal, President ISSH felicitating the Dr Venkataswami Orator, Dr. Fuminori Kanaya and Dr. Vikas Gupta

Dr. Bhangani, Organising Chairman, ISSH felicitating the BB Joshi Orator, Dr. P.C. HO

REPORT FROM HAND AND WRIST BIOMECHANICS INTERNATIONAL (HWBI)

HWBI 2015 Symposium
Milan, Italy
The Hand and Wrist Biomechanics International (HWBI) was formed to further enhance multidisciplinary and international collaborations related to hand/wrist biomechanics. The HWBI has established affiliations with the International Society of Biomechanics (ISB) and the International Federation of Societies for Surgery of the Hand (IFSSH). The HWBI is proud of these affiliations, which support the HWBI’s driving focus of advancing hand science by collectively addressing challenging clinical problems.

The HWBI has a long history of international symposia dating back to 1992. This year, the HWBI held its 9th Symposium at Milano Congressi in Milan, Italy from June 16-17, 2015. This year’s symposium was held in conjunction with the 20th Congress of Federation of European Societies for Surgery of the Hand (FESSH), June 17-20, 2015. The symposium program featured 56 presentations including keynotes, invited talks, and open paper submissions. Main topics covered at this year’s event included the wrist, carpal tunnel, finger mechanics, motor control, distal radial ulnar joint (DRUJ), distal radius, ligaments, tendons, and biomaterials. The 2015 symposium also featured the 2nd International Thumb Osteoarthritis Workshop. There was record attendance at this year’s event, with 102 participants including hand surgeons, hand therapists, and engineers from 16 countries. The HWBI is excited to continue building upon the excitement and success generated during the symposium.

For the first time, the HWBI awarded travel scholarships for the 2015 symposium to outstanding students, residents, and fellows. Four scholarships were generously sponsored by the ISB, HWBI, and William H. Seitz, MD Research Fund. An award committee was formed to select this year’s winners based on their abstract submissions to the symposium. The award winners were Joseph N. Gabra (USA), Benjamin Goislard de Monsabert (France), Faes D. Kerkhof (Belgium), and Giovanni F. Solitro (USA). The HWBI is grateful to the ISB and Dr. Seitz for their sponsorship and hopes to award even more scholarships at future symposia. For more information about the HWBI and its events, please visit the website at www.hwbi.org.

Conrad Weekes, Joyce, Kenneth Mary Joyce, George Rahamnai, Sean Michael Carroll, Jack Laurence Kelly, Padraic James Regan

408 Frequency of Scapholunate Ligament Injuries Associated with Distal Radius Shearing Fracture: Correlation of Fracture Patterns and Ligament Tear
Shiro Yoshida, Kenji Yoshida, Kensuke Sakai, Kenjiro Nakama, Naoto Shiba

410 Case Report
Hiroshi Yano, Naoto Shiba, Kenjiro Nakama, Kenji Yoshida

415 Audit of Clinical and Functional Outcomes of Arthroscopic Resection of Wrist Ganglions
Size-Fyn Chung, Shian Chao Tay

421 Bone Marrow Derived Mesenchymal Stem Cell Augmentation of Rabbit Flexor Tendon Healing
Min He, Aaron Wei Tat Gan, Amyr Ge Yu Tang Yim, James Cho Hong Koh, James Hoi Po Hui, Alphonous Khin Sze Chong

430 Supination and Pronation Strength Deficits Persist at 2-4 Years after Treatment of Distal Radius Fractures
Joris Ploegmakers, Bertram The, Allan Wang, Mike Brutty, Tim Ackland

435 Simple Trapeziectomy for Arthritis of the Basal Joint of the Thumb: 49 Cases Reviewed After Two Years
Kristine Elvebakk, Cecille Bendiksen Wold, Thomas Finzen, Harold Russwm, Volhammar Finsen

440 Kirschner Wire Exposure in Hand and Wrist Trauma
Mark H. Henry

447 One-Per-Mil Tumescent Infiltration Technique for Vascular Malformation Surgery in Hand and Upper Extremity: The Technique of H. Prasetyo, Jesslyn Gustin

453 Primary Index Finger Pollicization for Thumb Reconstruction Following Soft Tissue Sarcoma Excision
Venkata Satyanarayana Peddty, Adam Sierakowski, Madhu Periasamy, Shanmuganathan Raja Sabapathy

458 Fibro-Osseous Pseudotumour of the Digit: An Illustrative Case and Review of the Literature
Jeyun Zhou, Catrina McLean, Cameron Keating, James Finkemeyer, Adel Morsi

463 Thum Carpometacarpal Joint Stabilization in Ehlers-Danlos Syndrome - Case Report
Anca Nicoleta Breahna, Bryce Maurice Meads

466 Post Traumatic Avascular Necrosis of the Proximal Carpal Row - A Case Report
Ruben Manchera, Sandeep Jacob Sebastian, Mark Edward Puhaindran

471 Surgical Repair with External Fixation of Epiphyseal Fractures of the Proximal Phalanges of Three Fingers: A Case Report
Yasushi Morisawa, Shinichiro Takayama, Kazuki Sato

474 Attrition Rupture of the Flexor Pollicis Longus Tendon after Arthrodesis of the Trapeziometacarpal Joint: A Case Report

An extreme case of transcaphoid-transcapitate perilunate dislocation in an adolescent
K. Osman, P. Momoh, and A. Ruiz

Complex anterior dislocation of the metacarpophalangeal joint of the index finger: The ‘reverse-Kaplan’ injury
R. N. Green, P. R. P. Rushton, and D. J. Cloke

The treatment of bony mallet fingers using a triple K-wire fixation technique
B. Jiang, P. J. Wang, and J. J. Zhao

Acute ischemia of a thumb 10 years after revascularization
J. Couceiro, E. Moledo, and M. Sanmartin

Modified dorsal percutaneous screw fixation through a transtrapezial approach for scaphoid fractures
T. Kurahashi, T. Shinohara, and H. Hirata

Combined tendon avulsion and fracture in a mallet finger injury in a juvenile
J. P. A. Bellity and M. A. Tonkin

Effective bony mallet reduction using the principles of Elson’s test
A. Salibi and A. Barabas

Ulnar styloid fracture has no impact on the outcome but decreases supination strength after conservative treatment of distal radial fracture
S. Yilmaz, D. Cankaya, and D. Karakus

UPCOMING EVENTS

38ème CONGRÈS DU GAM
MEETING OF GAM
Group for the Advancement of Microsurgery
PARIS
27-28 MAI 2016
MAISON DE L’AMÉRIQUE LATINE

SUBMIT YOUR ABSTRACT

www.GAM-SFM.ORG

Thèmes / Themes

- Table ronde : Reconstruction microchirurgicale de la face - état de l’art
  Discussion: Facial microsurgical reconstruction: state of the art
- Table ronde : Techniques des transferts nerveux dans la paralysie du plexus brachial
  Discussion: Techniques in nerve transfers in brachial plexus palsy
- Conférence d’enseignement : Techniques de base en microchirurgie
  Instructional course: Basic techniques in microsurgery
- Conférence d’enseignement : Enseignement en microchirurgie : quel avenir ?
  Instructional course: Education in microsurgery: what the future?
- Conférences d’enseignement : Couverture des membres par lambeau libres
  Instructional course: Limb cover with free flaps
- Conférences d’enseignement : Technique avancées en microchirurgie : le transfert de pulpe digitale
  Instructional course: Advanced technique in microsurgery: finger pulp reconstruction
- Communications libres / Free papers
